Carbonaceous residues were formed by irradiation of thin layers of frozen methane at 10 to 15 K by 17 MeV protons and 3He ions and successive warming to ambient temperature. Analysis was performed by optical microscopy, scanning electron microscopy (SEM), Rutherford backscattering spectroscopy (RBS), elastic recoil detection analysis (ERDA), infrared spectroscopy (IR) in transmission, hydrogen nuclear magnetic resonance (1H-NMR), high performance liquid chromatography (HPLC) and gas chromatography–mass spectrometry (GC–MS). Long chain aliphatic and olefinic hydrocarbons constituted the main products. The formation of aromatic and polycyclic compounds, PAHs and amorphous carbon increased with the energy deposited in one collision cascade.

The linear energy transfer with respect to CH₄, Lₜ(CH₄), was varied in the systems p//Ar/CH₄ (12:1), p//CH₄ and 3He//CH₄ from 160 to 10×10⁶ eV km⁻¹, respectively. A threshold Lₜ for the formation of PAHs and related structures seems to range between 2 and 10 keVμm⁻¹. The experiments give evidence for a fast multicenter combination of intermediate radicals formed by the secondary suprathermal carbon atoms from knock on processes in one collision cascade. The experiments were aimed to simulate the effects of cosmic rays on primordial frozen matter. The results underline the role of heavier ion irradiation (He, etc.) in the prebiotic buildup of complex organic matter in space.

1. Introduction

Solid hydrocarbons from frozen CH₄ to polystyrene show formation of complex organic products when irradiated with energetic ions [1-10]. Hydrogen elimination, generation of unsaturated and cyclic structures and carbonization increases with radiation dose. It was, however, questionable whether the complex compounds were due to overall energy deposition or due to specific effects within the collision cascade, i.e. depending on a certain density of energy deposition [8,9]. It had been shown recently that in frozen CH₄ enclosed in metal cuvettes at 77 K, 3He⁺ ion bombardment induced the formation of polycyclic aromatic hydrocarbons (PAHs) [11,12]. CH₄ served as a deliberately model substance for complexation of organic matter starting from a primitive, primordial molecule. The formation of PAHs may be due to a multicenter reaction of secondary energetic carbon atoms and their intermediate products such as methylcarbene with the surrounding radicals [11-15]. This prompted a new study in frozen methane at 15 K using 17 MeV cyclotron ions in order to investigate possible mechanisms for the formation of defined classes of organic species and their dependence on increasing irradiation dose (D* = 0.07 to 16.8 eV per carbon atom) and energy density, expressed by the linear energy transfer with respect to CH₄, Lₜ(CH₄) = 161 to 10810 eVμm⁻¹. In the course of the irradiations it was distinguished between open targets (condensates on (111) Si wafer) which represent icy surfaces and CH₄ in metal cuvettes which represent the bulk of icy bodies, e.g. in the interior of comets [10-12]. The analyses of gases emanating during irradiation are reported in a parallel paper [16], those of the organic residues in this work.

2. Experimental

The gas condensation system and irradiation apparatus were described in refs. [15,16] in detail. Argon and methane gases were research grade (Ar: 99.999%; CH₄ 99.9995%; Messer Griesheim). 9.7 μm layers of CH₄/Ar (1:12) and 11 μm of CH₄ were condensed at 10–15 K and 2×10⁻⁵ mbar with a condensation rate of 145 μmole h⁻¹ on a (111) Si wafer attached to an aluminium cold finger. The ices were irradiated by 250 nAcm⁻² ion beams (fluence some 10¹⁵ cm⁻²) of 17.6 MeV protons and 16.9 MeV 3He⁺ ions of the CV 28 compact cyclotron of Forschungszentrum Jülich. After irradiation the cold finger was allowed to reach ambient temperature with heating rates of 0.1 to 0.5 Kmin⁻¹. The irradiated targets and the linear energy transfer values are summarized in table 1.
The solid residues were analysed in situ by visual inspection, optical microscopy, IR in transmission (293 K), SEM and RBS-ERDA. The soluble phase was dissolved in CDCl₃ (99.95%, Aldrich), and ¹H NMR (1 dim: H–H-shift correlated 2 D NMR (COSY)), HPLC and GC-MS spectra were recorded. The insoluble fraction on the Si wafer was analysed by IR in transmission at room temperature.

In situ and on-line determination of chemical modifications in closed targets was impossible. Consequently, their analysis was restricted to ¹H-NMR, HPLC and GC-MS.

3. Results

MeV ion irradiation with \( D^* = 0.07 \) to 16.8 eV per carbon atom converted the original CH₄ into an inhomogeneous solid residue with a thickness of 0.5 ± 0.2 \( \mu \)m, stable at room temperature. The IR spectra exhibit the dominance of typical aliphatic features such as \( \nu_\text{as}(C–H) \) sp³ CH₄ = 2955–2963 cm \(^{-1}\), \( \nu_\text{s}(C–H) \) sp³ CH₂ = 2926–2928 cm \(^{-1}\), \( \nu_\text{s}(C–H) \) sp³ CH₃ = 2870–2875 cm \(^{-1}\), \( \nu_\text{as}(C–H) \) sp³ CH₂ = 2853–2855 cm \(^{-1}\) and their corresponding \( \delta_{\text{as}}(CH₃) = 1450–1452 \) cm \(^{-1}\), \( \delta(CH₂) = 1370–1371 \) cm \(^{-1}\), \( \delta(CH₁) = 1460–1465 \) cm \(^{-1}\) and \( \tau(–(CH₂)ₙ–chain) = 722 \) cm \(^{-1}\) and \( \delta(C–C, –(CH₂)ₙ–chain) = 1298 \) cm \(^{-1}\). No olefinic, acetylenic or aromatic vibration modes were detected beyond a limit of about 1 pmol. With increasing irradiation dose the half widths of IR features became larger by a factor of 3 to 4. This and the decreasing transmittance of the base line can be interpreted in terms of an increase in aggregation.

This oligomerization coincides with a segregation of different phases, observed by optical microscopy and SEM. Fig. 1a for the lowest irradiation dose by 17.6 MeV protons on Ar/CH₄ exhibits a low variety of structures and only some small bubble like formations, whereas the irradiation at maximum dose and energy density results in an extreme inhomogeneous distribution of relative carbon intensity from 100% (black areas) to about 10% (gray) and 1% (white) and clear segregation of these three phases (fig. 1b and fig. 2).

The soluble fraction consists of about 90% linear alkanes, 5 to 6% linear alkylenes, both with ≤ 28 C atoms. The ¹H-NMR spectra show 4–5% unsaturated compounds as a first hint of hydrogen elimination (fig. 3); the position of organic sidegroups –R and aromatic structures Ar (= aryl) were calculated from H-increments and H–H-coupling constants.

dose range from 0.1 to 15 eV per carbon atom [11]. The H:C ratio of the residues obtained by irradiations of open CH₄ targets decreases from original 4 to a value of 1.4 (fig. 6), indicating that hydrogen elimination is favoured in open targets over closed systems.

4. Discussion

The dualism of irradiation dose and energy density seems to be an ideal tool to explain the experimental results.
The formation of a few % polycyclic aromatic hydrocarbons is governed by a critical linear energy transfer of about 2 to 10 keV·μm⁻¹ which induces a multizentrc reaction [11–15, 18], i.e. aggregation of the individual insertion products of hot carbon secondaries into CH₄ (in particular methylcarbene) and CH₂ and CH₃ radicals in one collision cascade. If L₄(CH₄) is below this critical value, the concentration of radicals in the activated zone is too low to recombine in the relaxation phase to complex two- or three-dimensional molecules.

In this conceptual framework, the total radiation dose which is correlated to overlapping cascades seems to be of minor importance in the buildup of PAHs compared to energy density effects. The classical hot atom reactions such as insertion, abstraction and addition [17] cannot explain the syntheses of PAHs. Radiative chemical mechanisms do not seem to play a role at 0.1 eV per carbon atom [11]. Successive reactions in overlapping cascades should contribute only with some 100 eV per carbon atom to a radiolytical formation of complex molecules.

This is important for space where the very long irradiation times at relatively low dose of 10⁻³ cm⁻² s⁻¹ of ions in the MeV region can lead to partial annealing of the defects. Thus, the necessary energy deposition and accumulation of subreaction-centers for the formation of PAHs hardly is reached by cascade overlap. This underlines the role of heavier ion irradiation in the prebiotic buildup of complex molecules. When performing simulation experiments on cosmic ray effects, more attention has to be given to these particles even when less abundant in space.

Last but not least, a clear separation between closed ice targets (bulk ices in the interior of comets, icy planets and satellites, etc.) and those exposed to vacuum (ice surfaces such as on interstellar and planetary grains) has to be taken into account. Bulk ices do not allow easy hydrogen release to space, and the molecules formed in the interior are protected against oxidation. Obviously, hydrogen elimination by hot atom chemistry and sputtering is more pronounced on ice surfaces where the different reduction potentials lead to different chemistry and an increasing carbonization. This could provide a potential source for amorphous carbon formation in space.

Acknowledgements

The authors thank Prof. Dr G. Götz, Jena, for helpful discussions of the RBS-ERDA spectra. They are indebted to the CV 2X cyclotron crew of Forschungszentrum Jülich for irradiations, Mrs. Karin Busse, Münster, for recording the NMR spectra, Dr. E. Wallura of IRW, Jülich, for SEM measurements and Hewlett Packard, Ratingen, for assistance in GC-MS.
